

Exhibit A

Supplement to:

G.D. Cooke and E.B. Welch, 2008 "Eutrophication of Tenkiller Reservoir, Oklahoma and Effects on Water Quality and Fisheries"

This supplement to the above named report summarizes new data collected in 2008. The inclusion of these 2008 data, with previous data in the report, clearly demonstrates that there has been no improvement in the condition of Tenkiller Reservoir, and illustrates the effect of low (2005, 2006, and 2007) and higher (1992, 1993, 2008) inflow water volumes on concentration of phosphorus (TP) in the reservoir. Simply stated, when there is a lot of water coming into the reservoir, there has been a lot of runoff from pastures treated with poultry waste, and P rich water is carried further into the reservoir. The condition of the reservoir only appears to be better in low inflow or drought years because less TP is exported from the pastures, and more TP settles to the bottom at the upper end of the reservoir because the water flow rate is low.

This effect is illustrated (upper bars) in Figures 7 and 8 supplements as a metric called water residence time (τ), the volume of the reservoir divided by its inflow rate. Lower τ values (1992, 1993, 2008) occur with higher inflows and are associated with more runoff, less settling of TP, and thus higher reservoir TP and chlorophyll. TP concentration is higher in reservoir surface waters when the reservoir is more highly flushed. (Jones et al. 2008).

Sampling and analytical procedures in 2008 were the same as described in the May, 2008 report. The data used for figures presented are included in the attached appendix.

The TP concentrations at LK-01 to LK-03, shown in Figure 7 supplement, were higher in 2008 than in 2007, 2006 or 2005, the three previous years for which data were collected by CDM for this project. That was largely due to the higher inflow and shorter τ in 2008. In fact, the TP value at LK-01 in June 2008 (58 $\mu\text{g/L}$) was the highest observed since 1993 (see appendix). As illustrated in Figures 7.1 and 7.2 supplements, TP was directly related to τ at LK-04, but inversely related to τ at LK-01 and 02, the lacustrine stations. The 2008 values for LK-04 and LK-01 are consistent with the previous data from the above report (Figures 7.1 and 7.2 supplements). Therefore, TP concentrations in the reservoir are to a large extent determined by τ , as well as by inflow concentration (Jones et al. 2008). That is because loss of TP from the water column decreases with shorter τ , and the momentum of higher inflow volumes carries incoming TP farther down the reservoir than is carried by lower inflow volumes. Also, shorter water residence time means more TP-laden runoff from pastures. Consequently, the deep lake-like zones (LK-01, 02) retain more TP in the epilimnion. Low inflow volumes (i.e., drought or longer τ), on the other hand allow for more TP to settle and be retained in sediment in the transition zone (LK-03) or be transported down reservoir at depth, below the epilimnion.

The lower TP concentrations at LK-04, with higher inflows (i.e. shorter τ), may be due to dilution of the TP load from bottom sediment (internal load), which would otherwise have more time to accumulate in the water column at lower inflow volume (i.e., longer τ).

Chlorophyll concentrations were also relatively high in 2008, in response to higher inflows (Figure 8 supplement). While chl was not always related to τ for all the data shown (e.g., chl was as high in 2005 as in 2008, despite a longer τ in 2005), there was usually a consistent

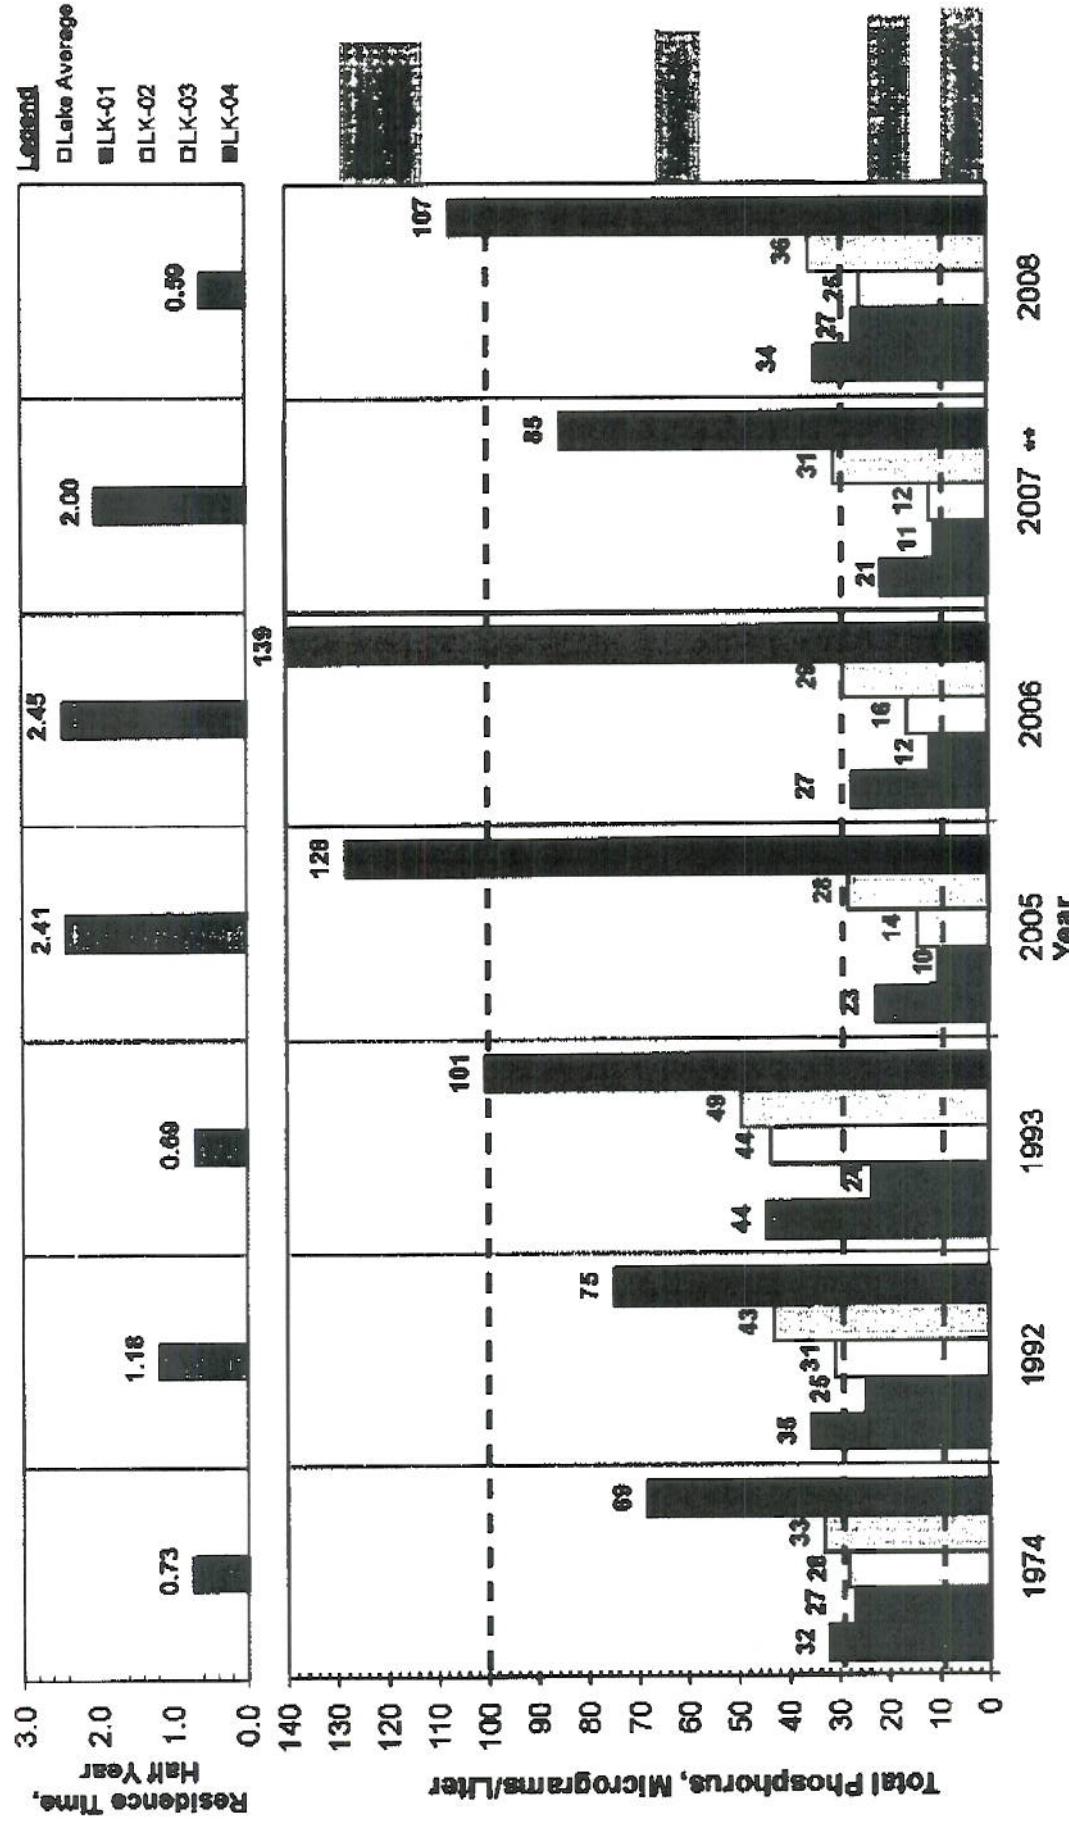

relation between TP and chl using all the data from Tenkiller, compared to a relation developed from 146 Missouri reservoirs (Figure 6, May 2008 report). Therefore, much of the year-to-year variation in chl can be ascribed to variation in TP.

Transparency in 2008 was not substantially different from that in 2007, but was less than in 2005 or 2006 (Figure 9 supplement). Non-algal turbidity also affects transparency, especially in high inflow years, so beside chl, that is some of the cause for low transparency in 2008.

Areal hypolimnetic oxygen deficit rate (AHOD) was higher in 2008, relative to most previous years, and similar to that in 2005 (Figure 29 supplement). High inflow should carry in more organic matter from external sources, as well as produce more algae in-lake from higher TP concentrations, and, therefore, result in higher AHODs. There is some tendency for short τ years to have higher AHODs; e.g., mean AHODs for 2002, 2004 and 2008 were over 1,500mg/m² per day, and they were short τ years. However, the AHOD exceeded that rate in 2005, and that was a long τ year. Long τ also allows more time for decomposition, and therefore higher AHODs, so there are competing forces involved, which attribute to the year-to-year variation and lack of obvious trends in AHOD. The AHOD in 2008 remained well above the eutrophic-hypereutrophic boundary.
